Abstract: Objective: Explain the influence of ruminal content (undigested feed) of beef with the addition of molasses in the ration on weight gain in guinea pigs (*Cavia porcellus*). **Method:** The rumen content of beef plus molasses was supplied as a food input to a sample of 40 growing-finished male guinea pigs from 30 to 90 days of age, as it is a valuable source of nutrients for animals due to its high contribution of protein and others. nutrients, and was supplemented with forage (chala) to cover the vitamin “C” that this species needs. The completely randomized statistical design (DCA) was used, with 10 guinea pigs for the control treatment and 30 guinea pigs for the experimental treatment distributed in three homogeneous groups as repetitions. (TE-R1; TE-R2; TE-R3). **Results:** The guinea pigs in the experimental group reached a final weight of 866.4 grams and the control group reached a final weight of 694 grams, achieving a total average weight increase of 172.4 grams. Greater than the guinea pigs in the control group in 60 days of experimentation. **Conclusions:** The reuse of bovine rumen content in guinea pig feeding generates greater weight gain and, consequently, guinea pig meat production increases.

Keywords: Guinea pig production, ruminal content, weight increase.

INTRODUCTION

The ruminal content of beef is found in its first stomach (rumen), which at the time of slaughter contains all the material that was not digested (Guerrero, 2004). A massive community of microorganisms lives in the rumen, mainly bacteria and protozoa, which ferment the food, delivering mainly volatile fatty acids (VFA) and carbon dioxide as products. VFA from the rumen reach circulation and are used by cattle as a primary source of energy and carbon (Domínguez, 2007).

Fermentation provides food and energy for the development of the microorganisms present in this gastric compartment, which, together with the undigested material, are subsequently removed more or less continuously from the rumen by passage to the other gastric compartments of the ruminant. The metabolic processes that occur there are similar to those carried out in monogastric animals and complete digestion in the abomasum and small intestine.

Rodríguez & Cook (2003) indicate that in the reticulum and rumen there are around 10 billion bacterial cells per gram of rumen content and around 200 species that are responsible for the greatest degradation of nutrients in the food content.

The ruminal microflora also has microscopic fungi that help in the digestion of food and belong to the Phylum Chytridiomycota of the Kingdom Fungi. Fungi were the last type of ruminal microorganisms to be discovered; Therefore, its mode of action to hydrolyze food particles is not well known. Ruminal fungi constitute about 8% of the microbial biomass and the zoospore population is estimated to have a density of 10,000 – 1,000,000 cells per milliliter of ruminal fluid.

Fungi are important in the digestion of fibrous foods during the first 5 hours after consumption; they produce an enzyme complex capable of degrading fiber as well as or better than the main cellulolytic bacteria, even being capable of dissolving part of the lignin.

Bacteria and protozoa act in the degradation of cellulose and its derivatives: hemicellulose, starch and proteins. Amylolytic activity is of great importance for these organisms. Protozoans digest starch and as the final product of metabolism produce volatile fatty acids, lactate, formate, H₂ and CO₂.

We noted that in Colombia, two processes have been implemented for the use of rumen

content in animal feed, one industrial Forage Flour (HF) and another semi-industrial called nutritional blocks, in our cases there is no literature cited other than an experience in direct feeding to sheep, this is partly because the proposed uses require the necessary infrastructure (Domínguez –Cota et al.,1994;Flores-Aguirre et al., 1994;Falla-Cabrera,1995)

Falla – Cabrera (1995) motivated by Domínguez (2007) Indicates that according to the bromatological analysis, the Ruminant Content contains: moisture 85%, protein – fat 9.60%, fiber 2.84%, ash 27.06%.

Rodríguez and Cook (2003) fattened guinea pigs using the content of bovine pre-stomachs, achieving a satisfactory weight increase.

The objective of this research work is to explain the influence of beef rumen content in the diet on weight gain in guinea pigs (*cavia porcellus*) from the territorial area of the Huacho District, Huaura Province, Lima-Peru.

MATERIALS AND METHODS

LOCATION

The research was carried out on the premises of the José Faustino Sánchez Carrión National University of Huacho, Province of Huaura.2017.

SAMPLE

We worked with a total of 40 male guinea pigs (*Cavia porcellus*) of 20 days of age on average, considering 10 guinea pigs for the control group (TC) and 30 guinea pigs for the experimental group (ET) distributed in 3 homogeneous groups, of 10 guinea pigs per group as repetitions, under the randomized experimental design (RCD).

INSTALLATIONS

The shed was built with materials from the area and in accordance with its ecology (Chauca, 1993). In the breeding shed, cages were installed in an area of 40 m², which were also used in the research, as follows:

- 06 breeding/lactation cages, 1m per side by 0.70m high.
- 03 breeding cages for males, 1m per side by 0.70m high.
- 03 breeding cages for females, 1m per side and 0.70m high.
- 03 individual cages for guinea pigs under observation (with health problems) measuring 1m per side by 0.70m high.

METHODOLOGY

The method was descriptive-experimental analytical type.

The bovine ruminal content (undigested feed) was collected immediately after the slaughter of bovines in the slaughterhouse, extracted from the pre-stomach called the rumen. It was then subjected to dehydration in the environment, and to improve the palatability of the food, 20% molasses was added.

The food was supplied ad-libitum to the experimental guinea pigs, complemented with forage (chala) to provide the vitamin “C” that this species needs, based on its nutritional requirements during the fattening stage; since these food inputs have a high percentage of protein, ash and fiber.

Weight control of the guinea pigs was carried out at 30 days of age on average and then biweekly until 90 days of age; having considered 10 days of adaptation in the consumption of the food that was the subject of the experiment.

| NUTRIENT | % |
|---------------|---------|
| Total protein | 18 – 20 |
| NDT | 56 –60 |
| Fiber | 9 – 18 |
| Fat | 1.0 |
| Calcium | 1.2 |
| Potassium | 1.4 |
| Match | 0.6 |

TABLE 01: NUTRITIONAL REQUIREMENTS OF THE GUINEA (Leonard, 1992)

RESULTS

The results of the research demonstrate that the provision of beef ruminal content (undigested food) in the diet of guinea pigs (*Cavia porcellus*) in experimentation it allowed them to achieve a greater weight (866.4 g) compared to the control group (694g) that received only a standardized conventional food ration (concentrate). An average increase of 172.4 g was achieved. in favor of the experimental group with three repetitions (TE-R1; TE-R2; TE-R3). Table: 06 and 07. Figure: 01 and 02.

One of the health problems of guinea pigs is gastrointestinal diseases, generally of bacterial etiology.

DISCUSSION

The richness in protein – fat (9.60%), ash (27.06%) and fiber (2.84%) of the ruminal content (undigested food) of beef, which indicates Falla – Cabrera (1995), mentioned by Domínguez (2007) credits and guarantees its reuse in animal feed; This agrees with the benefits achieved in terms of improved growth, weight gain and resistance to diseases reflected in the research guinea pigs.

As seen in Table 6 of the research, the experimental treatment reached a final average live weight of 866 grams at 90 days of age, achieving a weight increase of 172.4 grams in favor of the experimental group in 60 days of experimentation compared to the control group, which achieved a final average live weight of 694 grams, a result that agrees with the research of Rodríguez and Cook (2003) who carried out a similar study. Consequently, the rumen content of beef can be used as food for guinea pigs, with the additional benefit that it does not cause them, digestive pathologies.

CONCLUSIONS

- The results show that it is feasible to use the ruminal content (undigested food) of beef in the feeding of guinea pigs, thus allowing an increase in meat production of this species.
- Resistance to gastrointestinal diseases was observed in cattle.
